Installing Software

Really only two ways

Build (compile) from source

Copy binaries

Build

<u>Pros</u>

One set of files can support many "targets"
Relatively small packages

<u>Cons</u>

Requires a compiler on the target
Can be quite an involved process
Users get access to the source code
Publisher has less control

Copy Binaries

<u>Pros</u>

Publisher has a lot of control

Easier for user

<u>Cons</u>

More targets to maintain

More work for the publisher to package

Build Process

Acquire the source package (download, tape, CD)

Unpack the files (zip, tar)

Configure the build (configure script)

Build (make)

Install to final location (make install)

Copy Process

Copy the correct binaries to the correct spot on the system*

There are many ways to do this.

Copy Processes

Two basic strategies:

1) Simple copy

2) Provide some sort of install script

Copy or Build ???

Build is popular for FOSS

Build is popular with hackers

Copy is popular with administrators

Copy is popular with commercial software vendors

Basic Linux Software Management Structure

Packages (RPM, Debian Packages)

Package Manager (YUM, APT)

- YUM manages RPM packages
- APT manages Debian Packages

Commercial Unix systems have their own package management systems

RedHat Package Management

RPM

Each component is packaged into a single RPM file

File extension `.rpm` (`zip-3.0-1.el6.i686.rpm`)

Contains:

- Files

- Scripts

- Dependencies

Maintains a local database of what has been installed

RPM and Dependencies

Each package can require zero or more packages

Package will not install if dependencies are not present

This can be very frustrating to manage directly.

(we will get a glimpse at this frustration in the lab)

What can be done about this dependency problem?

Package Manager

Manages dependencies

RedHat Enterprise Linux uses Yellowdog Updater
Modified (YUM)

YUM

Groups packages into Repositories

Automatically resolves dependencies

Each distribution maintains repositories of packages <u>that have all been tested together.</u>

Repositories can be local or accessed over the 'Net

YUM and RHEL

To access RHEL update repositories a system must be licensed by Red Hat and must be registered with Red Hat.

Yum still works from local repositories, like we use in the labs.

RedHat offers a free license tier under the Red Hat Developer program

Should I use YUM, RPM, or Build?

A general rule of thumb…

Use the packages provided by your distribution if at all possible, they have been tested with each other.

Only resort to fetching individual RPMs or building from source when the software you need is not part of you distribution.

Demonstration

Let's walk through a few software installs like we will in the lab…
